ABSTRACT

We present the first multicolor view of the scattered light disk of the Herbig Ae star HD 163296, based on coronagraphic observations from the *Hubble Space Telescope* Advanced Camera for Surveys (*HST* ACS). Radial profile fits of the surface brightness along the disk’s semimajor axis indicate that the disk is not continuously flared, and extends to ~ 540 AU. The disk’s color $(V - I) = 1.1$ at a radial distance of $3.5''$ is redder than the observed stellar color $(V - I) = 0.15$. This red disk color might be indicative of either an evolution in the grain size distribution (i.e., grain growth) and/or composition, both of which would be consistent with the observed nonflared geometry of the outer disk. We also identify a single ansa morphological structure in our F435W ACS data, which is absent from earlier epoch F606W and F814W ACS data, but corresponds to one of the two ansae observed in archival *HST* Space Telescope Imaging Spectrograph (STIS) coronagraphic data. Following transformation to similar bandpasses, we find that the scattered light disk of HD 163296 is $1 \text{ mag arcsec}^{-2}$ fainter at $3.5''$ in the STIS data than in the ACS data. Moreover, variations are seen in (1) the visibility of the ansa(e) structures, (2) the relative surface brightness of the ansa(e) structures, and (3) the (known) intrinsic polarization of the system. These results indicate that the scattered light from the HD 163296 disk is variable. We speculate that the inner disk wall, which Sitko et al. suggests has a variable scale height as diagnosed by near-IR SED variability, induces variable self-shadowing of the outer disk. We further speculate that the observed surface brightness variability of the ansa(e) structures may indicate that the inner disk wall is azimuthally asymmetric.

1. INTRODUCTION

Investigations of the nature and evolution of dust grains in protoplanetary systems are motivated in part by our desire to understand the birth and evolution of planetary bodies, which originate from these systems. It is well established that Herbig Ae/Be stars (Herbig 1960) are intermediate-mass pre-main-sequence stars, analogous to the more familiar low-mass T Tauri stars, which contain copious amounts of circumstellar gas and dust (Waters & Waelkens 1998). A wealth of observational evidence (Mannings & Sargent 1997, 2000; Oudmaijer & Drew 1999; Vink et al. 2002; Eisner et al. 2004) suggests that the geometry of this gas and dust takes the form of a circumstellar disk. By contrast, our understanding of fundamental properties such as grain composition and size distribution, as well as the time evolution of these parameters, are much less understood.

Analysis of *Infrared Space Observatory* spectra led Meeus et al. (2001) to develop a two-part evolutionary classification of Herbig systems; Group I sources were characterized as being slightly younger systems with flared outer disks, while Group II sources

were characterized as slightly more evolved systems which have flatter disks owing to grain growth and settling. While Meeus et al. (2001) invoked dust settling to explain the differences in flaring between Group I and II sources, it has also been suggested that the outer regions of some Herbig disks may experience self-shadowing, owing to a “puffed-up” inner circumstellar disk rim (Natta et al. 2001; Dullemond et al. 2001; Dullemond & Dominik 2004a; Isella & Natta 2005). Recent models which include inflated inner disk rims have proven to be successful in explaining the near-IR and interferometric properties of several Herbig Ae stars (Isella et al. 2006). Conclusive confirmation of the geometry of the outer disk regions of Herbig Ae/Be stars inferred by spectral energy distribution (SED)—based studies has generally not occurred.

HD 163296 is a young (4 Myr; van den Ancker et al. 2000), nearby (122 pc; van den Ancker et al. 1998) Herbig Ae star. While the star is not deeply embedded in a natal star formation dust cloud (Thé et al. 1985), it still displays clear signs of active accretion via the presence of jets and Herbig-Haro knots (Grady et al. 2000; Devine et al. 2000; Wassell et al. 2006). Hence, HD 163296 appears to be in a transition phase between optically thick, extremely young pre-main-sequence stars and the much more optically thin, near zero-age main sequence debris disk type stars (Ardila et al. 2004; Kalas et al. 2005, 2006; Golimowski et al. 2006). Indirect techniques (Bjorkman et al. 1995) and resolved imaging (Mannings & Sargent 1997; Grady et al. 2000; Isella et al. 2007) have confirmed the presence of a circumstellar disk associated with HD 163296. *Hubble Space Telescope* Space Telescope Imaging Spectrograph (*HST* STIS) white-light coronagraphic observations spatially resolved the outer regions of this disk, and detected evidence of disk structure including an inner annulus of reduced scattering and a bright outer ring or ansae of

material (Grady et al. 2000). The inner region of HD 163296’s circumstellar disk, as diagnosed by near-IR (0.8–5 μm) SED monitoring, exhibits evidence of variability, possibly owing to changes in the inner disk wall (Sitko et al. 2008).

Attempts to link processes which dominate the inner regions of Herbig Ae disks to morphological features observed in the outer disk regions, i.e., determining the relative roles of self-shadowing, dust settling, and disk flaring (Dullemond & Dominik 2004a), requires a wealth of observational data which diagnose the inner and outer disk regions. In this paper, we present a multiepoch, multicolor view of the HD 163296 scattered light disk, providing a significant improvement in the documented behavior of the outer regions of HD 163296’s circumstellar disk. We describe the observational details and data reduction procedures applied to our Advanced Camera for Surveys (ACS) data in § 2. In § 3 we document the basic features of the HD 163296 scattered light disk in our ACS data, and compare these results to earlier epoch scattered light imaging in § 4. The possible mechanisms which might explain the observed scattered light variability are discussed in § 5. We provide a summary of our main results in § 6.

2. OBSERVATIONS AND DATA REDUCTION

We obtained coronagraphic imaging of HD 163296 in the *HST* ACS F435W filter via the cycle 12 GTO program 9987, and in the ACS F606W and F814W filters via the cycle 11 GTO program 9295. All observations utilized the coronagraphic mode of the High Resolution Channel (HRC) camera, along with its 1.8" diameter occulter spot, yielding a $29.2'' \times 26.2''$ field of view at a pixel scale of $0.028'' \times 0.025''$. The FWHM of the point-spread function (PSF) of the HRC is 50 mas in *V*. Our science target data were obtained at two different *HST* roll angles to better facilitate the separation of PSF artifacts from real structures. The A3 IV star HD 145570, selected for its spectral match to HD 163296, was used as a PSF reference, and was observed in orbits immediately following our HD 163296 exposures. A summary of the basic parameters of our data set is presented in Table 1.

The standard *HST* pipeline was used to perform basic initial data reduction procedures. We used the best available calibration files for this processing, including a correction for the different flat-field illumination of the region nearby the coronagraphic spot. Cosmic-ray split images were combined using standard pipeline techniques.

Techniques to identify and remove PSF signatures from *HST* ACS coronagraphic data are well documented in the literature (Clampin et al. 2003; Golimowski et al. 2006). Following these

established procedures, we first normalized and aligned the nondistortion-corrected images of our PSF reference star to HD 163296 in an iterative manner, using a cubic convolution interpolation function. Residual alignment errors in the resulting best subtraction are of order ± 0.05 pixels (Pavlovsky et al. 2005), and our normalization is accurate to $\sim 2\%$ (Clampin et al. 2003). Following the subtraction of a fully registered and scaled PSF, we used MultiDrizzle to correct our data for the known geometric distortion of the HRC field of view and rotate all images into a common orientation.

Next, SYNPHOT, the synthetic photometry package within STSDAS, was used to determine the correction factor needed to calibrate our data to an absolute photometric scale. As a template for HD 163296, we used a synthetic spectrum of 69 Her (A2 V), normalized to the *V*-band magnitude of HD 163296, 6.899; a synthetic spectrum of 59 Her (A3 III), normalized to a *V*-band magnitude of 4.940 served as a template for HD 145570. The ratio of the stellar flux between HD 163296 and HD 145570, extracted both from our coronagraphic images and our synthetic representations of these data, were consistent to $< 2\%$ over multiple filter combinations, indicating that our choice of synthetic spectra were reasonable. All PSF-subtracted, distortion-corrected images were normalized to the synthetic flux of HD 163296, and the different roll angle images were combined to increase the effective signal-to-noise ratios (S/Ns). Note that all surface brightnesses reported in the native ACS filter bandpasses are based on the STMAG photometric system, and have been corrected for the known achromatic 52.5% reduction of flux induced by the coronagraph.

3. DISK CHARACTERISTICS DERIVED FROM *HST* ACS OBSERVATIONS

Figures 1, 2, and 3 present the PSF-subtracted, roll angle combined, calibrated images of HD 163296 in the F435W, F606W, and F814W filters, respectively, using a square root intensity stretch and a 3 pixel Gaussian kernel smoothing function. We have masked regions interior to a radial distance of $2.0''$, which are dominated by PSF subtraction residuals. Note that several apparent features in these figures are actually well-known instrumental artifacts, whose characteristics and origin are discussed in depth elsewhere (Clampin et al. 2003; Krist et al. 2005a; Gonzaga et al. 2005). All narrow radial spikes are residuals due to incomplete PSF subtraction. In addition, image imperfections arising from the $3.0''$ diameter occulter spot and its occulter finger are clearly seen in all images (west-northwest of the central source in the F435W filter; east-southeast of the central source in the F606W and F814W filters). This occulter finger and spot also projects

FIG. 1.—PSF-subtracted, two roll angle combined image of HD 163296 in the F435W filter. The image, which has a field of view of $20.0'' \times 20.0''$, has been plotted using a square root scale, smoothed with a 3 pixel Gaussian kernel. Regions inside a radial distance of $2.0''$ were dominated by PSF subtraction residuals and were masked from the displayed data.

“horn-shaped” artifacts located at a distance of $2.25''$ – $3.0''$ from the central source.

Three Herbig-Haro knots and a bipolar jet are clearly visible in our multipoch images; these features have been identified in previous investigations (Grady et al. 2000; Devine et al. 2000),

FIG. 2.—HD 163296 in the F606W filter, using the same parameters as in Fig. 1.

FIG. 3.—HD 163296 in the F814W filter, using the same parameters as in Fig. 1.

and Wassell et al. (2006) have used some of these data to estimate both the proper motion of the knots and the mass-loss rate of the HD 163296 system. Having identified these known features and artifacts of our data, we now focus on describing the radial and azimuthal surface brightness, color, and morphological features of the HD 163296 disk.

3.1. Disk Surface Brightness

While the surface brightness profile of portions of the HD 163296 disk were characterized via white-light STIS coronagraphic imaging (Grady et al. 2000), the large occulting wedges used by this coronagraph prevent an investigation of the full radial and azimuthal structure of the disk. Our ACS images do not suffer from such artifacts; hence, we are able to provide the first complete, multicolor assessment of the HD 163296 disk.

We first calculate the disk surface brightness along the semi-major axis, as reported by Grady et al. (2000) and Wassell et al. (2006). We extracted 10 pixel wide ($0.25''$) radial profile cuts at position angles of 132° and 312° measured north to east, and subsequently combined these data in 4 pixel ($0.10''$) bins (see Fig. 4). As illustrated in Figure 5 for our F606W data, these radial profiles followed three distinct power-law trends. Between $\sim 2.2''$ and $\sim 2.8''$, evidence of scattered light is apparent; however, it is likely that PSF subtraction residuals at least partially contribute to this measured flux. Clear evidence of the scattered light disk is seen in all filters from $\sim 2.9''$ to $\sim 4.4''$ (350 – 540 AU). The abrupt turnover in the profiles at radial distances $>4.4''$ (540 AU) represents the termination of our detection of the disk; this boundary could either indicate the physical outer radius of the disk’s upper atmosphere or merely the radial location at which the disk becomes extremely optically thin.

Table 2 lists the exponents of the best power-law fits derived along the disk major axis in each of our three filters. Concentrating on the $\sim 2.9''$ to $\sim 4.4''$ regions over which we are clearly seeing the scattered light disk, several features and trends are apparent. At the level of the S/N of our data, we do not detect

FIG. 4.— Ten pixel wide ($0.25''$) median radial surface brightness cuts along the semimajor axis (P.A. = 132° and 312°) of the HD 163296 scattered light disk. The data were subsequently combined into 4 pixel ($0.10''$) wide bins. The colored horizontal lines denote the background sky surface brightness in each filter.

clear evidence of differences between the surface brightness behavior in the southeast versus northwest quadrants of the disk in the F606W and F814W filters. Note that the southeast quadrant of our F435W disk major-axis radial profile cut is “contaminated” by the presence of an ansa feature, which will be discussed in § 3.3.

3.1.1. Disk Size

A large range of sizes has been suggested for the HD 163296 circumstellar disk. Dominik et al. (2003) assumed an outer radius of 50 AU in their SED fitting of the system. Isella et al. (2007) reported that CO emission, likely produced in the upper layers of the disk, extended out to a radial distance of 540 AU; moreover, they reported an unexpected deficit of millimeter continuum emis-

sion beyond 200 AU, which they interpreted as evidence that the disk was strongly depleted of dust outside of 200 AU. Isella et al. (2007) speculated that this deficit could be due to the inward migration of large bodies in the disk or due to clearing by a low-mass companion.

Our spatially resolved imagery reveals that light scattering off of dust residing in the upper layers of the HD 163296 disk extends out to a radial distance of ~ 540 AU. Given our detection, we suggest that there is no physical gap of dust at radial distances greater than 200 AU, as hypothesized by Isella et al. (2007). Rather, we suggest that some of the alternate interpretations discussed in Isella et al. (2007) might provide more feasible explanations for the nondetection of dust millimeter continuum emission beyond 200 AU, including grain growth and/or a change in the disk

FIG. 5.— Power-law fits to the surface brightness along the southeast (left) and northwest (right) regions of the semimajor axis in the F606W filter. The radial profiles were determined from the median of 10 pixel wide ($0.25''$) cuts across the disk major axis, which were subsequently combined in 4 pixel ($0.10''$) radial bins. Three distinct fitting regions, $2.2''$ – $2.8''$, $2.9''$ – $4.4''$, and $4.5''$ – $6.1''$, denoted in this figure by different color schemes, yielded the power-law parameters listed in Table 2. A similar analysis was performed for the F435W and F814W data.

TABLE 2
POWER-LAW EXPONENTS OF DISK MAJOR-AXIS RADIAL PROFILES

Filter-Disk Quadrant (1)	Region 1 (2.2''–2.8'') (2)	Region 2 (2.9''–4.4'') (3)	Region 3 (4.5''–6.1'') (4)
F435W-NW.....	1.4 ± 1.1	3.7 ± 0.3	2.2 ± 0.6
F435W-SE.....	4.9 ± 1.1	5.3 ± 0.4	1.5 ± 0.5
F606W-NW.....	0.5 ± 0.8	4.6 ± 0.2	1.1 ± 0.2
F606W-SE.....	–1.0 ± 0.4	3.9 ± 0.1	1.3 ± 0.2
F814W-NW.....	2.4 ± 0.5	3.7 ± 0.3	0.4 ± 0.3
F814W-SE.....	–0.7 ± 0.6	3.2 ^a ± 0.4	0.7 ^b ± 0.3

NOTES.—Power-law fits to the surface brightness along the southeast (left) and northwest (right) regions of the semimajor axis in the F606W filter. The radial profiles were determined from the median of 10 pixel wide (0.25'') cuts across the disk major axis, which were subsequently combined in 4 pixel (0.10'') radial bins. Radial profile cuts at a disk position angle of 132°, measured north to east, sampled the southeast (SE) disk quadrant, while cuts at a disk position angle of 312° sampled the northwest (NW) disk quadrant.

^a Fit regions which were truncated from that listed in Col. (3) include: 3.1''–3.7'' and 4.4''–4.5''.

^b Fit regions which were truncated from that listed in Col. (4) include: 4.6''–6.1''.

geometry beyond 200 AU (assumed by Isella et al. [2007] to be a fully flared disk).

3.1.2. Disk Geometry

Power-law fits to scattered light imagery provide one the means to diagnose the geometry of Herbig Ae circumstellar disks (see, e.g., Grady et al. 2007). As seen in Table 2, the surface brightness of the HD 163296 disk in the ACS F435W, F606W, and F814W filters follows an $\sim r^{-4}$ dependence. These data clearly deviate from the expected behavior of a continuously flared disk, which would follow an r^{-2} dependence, or a geometrically thin disk, which would follow an r^{-3} dependence (Whitney & Hartmann 1992). Dominik et al. (2003) also reached the conclusion that the HD 163296 disk was not continuously flared based on SED modeling, although some of the parameters adopted in their model which produced this result (i.e., a disk outer radius of 50 AU) are dubious.

3.2. Disk Color

Our multifilter *HST* ACS data set also allows us to provide the first measurement of the color of HD 163296's scattered light disk. We first calculated the surface brightness at radial distances

of 3.0'' and 3.5'' along the disk semimajor axis (P.A.s of 132° and 312°). The median flux within 1.0'' × 1.0'' apertures were determined at each location, and complimentary measurements (P.A.s of 132 and 312) were averaged to produce the surface brightnesses listed in Table 3. Given our previous assessment that PSF subtraction residuals could be contributing to the observed scattered light inside a radial distance of 2.9'', we caution that our aperture photometry at 3.0'' similarly might be *marginally* contaminated: by contrast, the aperture photometry at 3.5'' should be free from such effects. Background sky surface brightnesses (Table 3) were determined by averaging the median pixel values in two 1.0'' × 1.0'' apertures located 9.0'' from the central star. The standard deviation of these background sky apertures were used to provide an estimate of the photometric uncertainties within our science apertures at 3.0'' and 3.5'' along the disk semimajor axis.

The surface brightnesses in each of our ACS filters (Table 3) were converted to the standard *BVI* system by iteration of the transformation equation outlined by Sirianni et al. (2005): $\text{TMAG} = \text{SMAG} + c_0 + c_1 \times \text{TC} + c_2 \times \text{TC}^2$, where TMAG is the Johnson *B*, *V*, or *I* magnitude, SMAG is the ACS filter magnitude in the OBMAG photometric system, TC is the OBMAG color difference of the filters used, and c_0 , c_1 , and c_2 are transformation coefficients tabulated by Sirianni et al. (2005). Note that the *B*-band surface brightness and (*B* – *V*) color were calculated using multi-epoch data, while *V*- and *I*-band surface brightnesses and (*V* – *I*) color were calculated using single-epoch data (see Table 4).

The observed disk (*V* – *I*) color 3.5'' from the central star along the semimajor axis, 1.1, is significantly redder than literature measurements of the stellar (*V* – *I*) color, 0.15 (Thé et al. 1985). To better assess the global behavior of the disk's color, we transformed our F606W and F814W imagery to the Johnson *V*- and *I*-band filters using the aforementioned techniques. The resulting (*V* – *I*) image of the scattered light disk, plotted on a linear scale and smoothed with an 8 pixel Gaussian kernel, is shown in Figure 6. From inspection of Figure 6, we conclude that our data provide no clear evidence of a spatial dependence in the (*V* – *I*) color of the scattered light disk.

With the exception of AU Mic (Krist et al. 2005a), the colors of many other resolved disk systems are similarly redder than their host stars (HR 4796A, Schneider et al. 1999; HD 141569A, Clampin et al. 2003; GG Tauri, Krist et al. 2005b; β Pic, Golimowski et al. 2006). As discussed for these aforementioned systems, disk colors have been used to provide tentative constraints on the relative size distribution and/or chemistry of grain populations,

TABLE 3
SURFACE BRIGHTNESSES

Filter	Disk Major Axis (3.0'') (mag arcsec ⁻²)	Disk Major Axis (3.5'') (mag arcsec ⁻²)	Background Sky S.B. (9.0'') (mag arcsec ⁻²)
ACS F435W.....	19.6 ± 0.1	20.1 ± 0.2	22.3
ACS F606W.....	18.6 ± 0.2	19.2 ± 0.2	20.6
ACS F814W.....	19.1 ± 0.2	19.4 ± 0.2	20.8
ACS (F606+F814) _{ave}	18.9 ± 0.2	19.3 ± 0.2	20.7
ACS (F435+F606+F814) _{ave}	18.7 ± 0.2	19.1 ± 0.2	20.7
STIS Clear.....	20.0 ± 0.1	20.3 ± 0.2	21.8

NOTES.—Disk surface brightnesses, calculated by median averaging 1.0'' × 1.0'' apertures placed at radial distances of 3.0'' and 3.5'' along the disk major axis (P.A. = 132°, 312°, measured north to east) are cited in the STMAG photometric reference frame. The background sky surface brightnesses were determined by averaging the median pixel values within two 1.0'' × 1.0'' apertures located 9.0'' from the central star. As discussed in § 4, the ACS (F606W+F814W)_{ave} and ACS (F435W+F606W+F814W)_{ave} data correspond to weighted averages of single- and multi-epoch ACS data, respectively, which were combined to crudely approximate the STIS clear filter bandpass.

(<i>V</i> – <i>I</i>).....	0.7 ± 0.3	1.1 ± 0.3

NOTES.—The disk surface brightnesses quoted in Table 3 were converted to the standard Johnson *UBVRI* system. Transformations of the ACS data were achieved using the iterative technique outlined by Sirianni et al. (2005).

^a Data derived via multiepoch ACS observations.

although degeneracies clearly exist in such an analysis (e.g., McCabe et al. 2002). One possible interpretation of a red disk color is that some amount of grain processing has occurred (i.e., grain growth; chemistry evolution). Grain growth and grain settling is a phenomenon which is believed to occur in Herbig Ae disks (van Boekel et al. 2003; Acke et al. 2004; Dullemond & Dominik 2004a, 2004b), and is generally associated with systems whose outer disks are not continuously flared. Previous analysis of the IR SED of HD 163296 has led to suggestions that this disk system has experienced grain growth and settling (Meeus et al. 2001). The detection of a noncontinuously flared disk and red (*V* – *I*) disk color from our spatially resolved scattered light imagery is thus consistent (although not conclusive) with such a phenomenon occurring. We also note that our HD 163296 imagery does not exhibit significant evidence of a scattering asymmetry due to differences in forward- and backscattering of grains in the disk, as is seen in systems such as GG Tauri (Krist et al. 2005b). Future modeling efforts which utilize both the known SED properties (Meeus et al. 2001) and scattered light properties (the present study) of the HD 163296 disk would help to better constrain the grain size distribution in a more quantitative manner.

3.3. Morphological Features

The superlative spatial resolution of the *HST* ACS allows for the search of both radial and azimuthal morphological structures within the HD 163296 scattered light disk. Simple visual inspection of our F606W and F814W images (Fig. 7) reveals no clear evidence of disk structure. By contrast, our later epoch F435W data (Fig. 7) clearly exhibit evidence of an ansa-like structure in the southeast quadrant of the disk, located at the same position of one of two ansae noted in archival *HST* STIS coronagraphic observations (Grady et al. 2000). The ansa is visible and stationary in both of the roll angle images at F435W, whereas PSF subtraction artifacts rotate with the roll angle; moreover, this structure is not associated with the horn-shaped artifacts attributable to the ACS large occulting spot and finger.

We extracted 10 pixel wide (0.25'') median-averaged radial profile cuts from our data to parameterize this disk structure. The bottom panels of Figure 8 depict the radial surface brightness profiles, in 3 pixel (0.075'') radial bins, at position angles of 140° north to east (southeast disk) and 320° north to east (northwest disk) for our three bandpasses. At its brightest point, a radial distance of ~3.1''–3.2'', the structure has a F435W surface brightness of ~19.5 mag arcsec⁻², and is preceded by sudden dimming in surface brightness. At slightly different position angles, 130° north to east and 310° north to east (see top panel, Fig. 8), the feature is slightly brighter (F435W ~ 19.0 mag arcsec⁻²), character-

FIG. 6.—A 14.5'' × 14.5'' (*V* – *I*) color image of the HD 163296 scattered light disk plotted on a linear scale, smoothed with a 8 pixel Gaussian kernel. Regions inside a radial distance of 2.0'' are masked, and the large white circle corresponds to a radial distance of 4.0''. The color of the scattered light disk is similar to that of the three HH knots visible, and exhibits no significant evidence of systematic spatial variations at the S/N level of our data.

ized by a less steep dimming in surface brightness, and reaches a peak flux at a slightly more interior radial distance. At both position angles, no corresponding structures are seen either in the northwest cut of the F435W data or the southeast and northwest cuts of the F606W and F814W data. Note that the apparent “feature” in the F814W filter (and less apparent in the F606W filter) data at 3.5'' in the northwest disk quadrant is merely a background star. It is quite clear that the overall surface brightness of the F435W data at the radial distance of the feature (~3.0'') is brighter in the southeast region of the disk than in the northwest region of the disk.

4. THE MULTIEPOCH BEHAVIOR OF THE HD 163296 SCATTERED LIGHT DISK

Grady et al. (2000) presented white-light *HST* STIS coronagraphic observations of HD 163296, obtained in 1998 September. The STIS observations were characterized by a featureless signal from 1.5'' to 2.5'', a darker zone at 2.65'' of width 0.4'', and two bright ansae peaking at 2.9'' in the southeast quadrant and 3.2'' in the northwest quadrant (see Fig. 7). Grady et al. (2000) considered two primary explanations for the observed bright ansae and dark lanes in their STIS imagery, changes in the dust grain composition, and dynamical clearing by planetary-like bodies, although they noted that other possibilities could not be excluded.

Comparison of these archival white-light ($\lambda_{\text{central}} = 5850 \text{ \AA}$, $\Delta\lambda = 4410 \text{ \AA}$) STIS data with our multiepoch F435W ($\lambda_{\text{central}} = 4297 \text{ \AA}$, $\Delta\lambda = 1038 \text{ \AA}$), F606W ($\lambda_{\text{central}} = 5907 \text{ \AA}$, $\Delta\lambda = 2342 \text{ \AA}$), and F814W ($\lambda_{\text{central}} = 8333 \text{ \AA}$, $\Delta\lambda = 2511 \text{ \AA}$) ACS observations requires caution, given the different bandpasses sampled by each individual observation. Our single-epoch F606W and F814W observations span most of the STIS bandpass. To serve as a crude, approximate template for comparison to the archival STIS images, we have combined our ACS F606W and F814W data after first

FIG. 7.— The 1998 epoch *HST* STIS clear filter (*upper left*), 2003 epoch *HST* ACS F606W (*upper right*), 2003 epoch *HST* ACS F814W (*lower left*), and 2004 epoch *HST* ACS F435W (*lower right*) coronagraphic observations of HD 163296. The field of view for all images is $12.0'' \times 12.0''$; all images are plotted on a square root stretch scale smoothed by a second-order Gaussian function, except for the STIS image, which is smoothed with a first-order Gaussian. Regions inside a radial distance of $2.0''$ are masked, and the large black circle corresponds to a radial distance of $4.0''$.

FIG. 8.—*Bottom*: The median average of 10 pixel wide ($0.25''$) radial profile cuts, subsequently averaged in bins 3 radial pixels wide, calculated at position angles of 140° and 320° , measured north to east. These cuts clearly depict the behavior of the spiral arm structure observed in the southeast disk quadrant of the F435W data (at a radial distance of $\sim 3.0''$ – $3.5''$). The dashed horizontal lines represent the limiting surface brightness magnitudes for each bandpass, while the vertical lines depict the three regions characterized by distinctive power laws in Table 2. *Top*: The median average of 10 pixel wide radial profile cuts, subsequently averaged in 3 (radial) pixel bins, calculated at position angles of 130° , 140° , 310° , and 320° for the F435W data.

normalizing the images to account for the different throughput of these filters, ~ 0.16 for F814W and ~ 0.26 for F606W. Hereafter we refer to this combination as our ACS F606W+F814W data set. Similarly, *under the assumption that the HD 163296 disk surface brightness is not variable*, we have combined our different epochs of ACS data, again after normalizing the images to account for the different throughput of the filters, ~ 0.16 for F814W, ~ 0.26 for F606W, and ~ 0.19 for F435W. We will refer to this latter combination, which covers the majority of the STIS clear filter bandpass, as our ACS F435W+F606W+F814W data set.

4.1. Disk Surface Brightness

Mirroring the analysis performed in § 3.2, we calculated the average disk surface brightness along the semimajor axis of the disk, at radial distances of $3.0''$ and $3.5''$ from the central star. These surface brightness measurements are listed in Table 3; we also report the surface brightness of the STIS epoch data in the Johnson V band in Table 4. We stress that this quoted V -band surface brightness, calculated via a transformation equation which incorporated our observed $(V - I)$ disk color, is *only a crude approximation*.

The 1998 STIS epoch surface brightness along the major axis of the HD 163296 scattered light disk is significantly fainter than all other measurements in all other filter bandpasses. In the Johnson V -band system, the 1998 STIS observation at a radial distance of $3.5''$ from the central star ($20.1 \text{ mag arcsec}^{-2}$) is $\sim 1 \text{ mag arcsec}^{-2}$ fainter than the 2003 ACS V -band surface brightness ($19.2 \text{ mag arcsec}^{-2}$; see Table 4). In the instrumental filter system, the 1998 STIS clear filter surface brightness at a radial distance of $3.5''$ from the central star ($20.3 \text{ mag arcsec}^{-2}$) is similarly $\sim 1.0 \text{ mag arcsec}^{-2}$ fainter than that measured in both of our ACS “white-light” filter approximation data sets (19.3 and $19.1 \text{ mag arcsec}^{-2}$, respectively; see Table 3). As the 1998 epoch STIS data are significantly fainter than that measured in each bandpass of our ACS data, it is clear that no combination of the ACS data can reproduce the behavior of the STIS scattered light surface brightnesses. We suggest that the observed multipepoch behavior of the disk’s surface brightness is *one* piece of evidence which suggests that the system’s scattered light disk is variable.

4.2. Morphological Features

Grady et al. (2000) reported the presence of two ansae in the white-light STIS coronagraphic image of HD 163296 obtained in 1998, with the brightest ansa located in the northwest quadrant of the disk. In § 3.3 we reported a null detection of any morphological features in our 2003 epoch data (F606W and F814W filters) and the detection of a single ansa structure in the southeast quadrant of our *HST* ACS F435W data. The variability in the visibility of these morphological features are easily seen in Figure 7.

To compare and contrast these features in a quantitative manner, we have followed the technique outlined in § 3.3 and extracted radial surface brightness profiles for the ACS F606W+F814W and STIS data (see Fig. 9). Note that our ACS radial profile cuts correspond to the median average of a 10 pixel wide ($0.25''$) aperture which were subsequently averaged in 3 (radial) pixel bins, while our STIS radial profile cuts correspond to the median average of a 5 pixel wide ($0.25''$) aperture which were subsequently averaged in 3 (radial) pixel bins.

It is clear that the ansa structure we reported in our ACS F435W data in the southeast quadrant of the disk (*top left panel*, Fig. 9) occurs at the same radial distance as the ansa in the southeast quadrant reported by Grady et al. (2000); hence, it is plausible to suggest that these morphological features are in fact the same phenomenon. Interestingly, while the ansa is brighter in the northwest quadrant than in the southeast quadrant in the STIS data, a nearly opposite scenario characterizes the ACS F435W data, such that the ansa is present in the southeast quadrant and absent in the northwest quadrant. The ansa features which characterize the HD 163296 scattered light disk not only exhibit variability in the epochs in which they are discernible, but also exhibit different surface brightnesses in the epochs in which they are visible.

The nondetection of these morphological features in our 2003 epoch data are unlikely to be due to the sensitivity limits of our data. Ignoring the obvious differences in bandpasses, the observed surface brightness of our ACS data which fail to detect any morphological features (2003; F606W, F814W) are actually brighter than that observed in our ACS data, in which structure is detected (2004; F435W). Moreover, the limiting magnitude of our 2003 ACS data, depicted as dashed horizontal lines in Figure 8, is $1 \text{ mag arcsec}^{-2}$ below the measured surface brightness of the morphological feature in our 2004 epoch F435W data, inside of a radial distance of $3.5''$.

FIG. 9.—*Bottom*: The median average of $0.25''$ wide radial profile cuts, shown for all data sets, calculated at position angles of 140° and 320° , and subsequently averaged in bins 3 radial pixels wide. Note that the epochs characterized by low overall surface brightness profiles (STIS, pink; ACS F435W, blue) are also the epochs in which spiral arm structure(s) are observed in the disk. The dashed horizontal lines represent the limiting surface brightness magnitudes for each bandpass, while the vertical lines depict the three regions characterized by distinctive power laws in Table 2. *Top*: The median average of $0.25''$ wide radial profile cuts are shown for all epochs which exhibit spiral arm structure(s).

One might also reason that, given the different bandpasses probed by our multiepoch ACS and STIS data, perhaps the visibility of the morphological structure is an optical depth effect, and is extremely color-dependent (i.e., produced by small particle size scatterers). Given the very red ($V - I$) color of the disk (§ 3.2), we suggest that this scenario is dubious. Moreover, it is difficult to envision how an optical depth phenomenon could simultaneously explain both the visibility pattern (visible in 1998 white light; 2004 F435W) and surface brightness variability (northwest ansa brighter than southeast ansa in 1998; southeast ansa brighter than [nondetected] northwest ansa in 2004) of these morphological features. Rather, we suggest that the visibility and surface brightness variability of these morphological features are *two* additional pieces of evidence which suggest that the system's scattered light disk is variable.

We also note that unresolved linear spectropolarimetric monitoring of HD 163296 has revealed evidence of a time-variable intrinsic polarization component (K. S. Bjorkman 2007, private communication). Such data indicate variability in the net (unresolved) scattered light behavior of the system. As the integrated scattered light of HD 163296 exhibits variability, we suggest it is perhaps not surprising to find evidence that when this scattered

light is resolved via coronagraphic imaging, one finds multiple avenues of evidence indicating variability.

5. ORIGIN OF THE OBSERVED SCATTERED LIGHT VARIABILITY

Our analysis of multiepoch, multicolor, spatially resolved imagery of HD 163296 suggests that its scattered light disk is variable; we observe a ~ 1 mag arcsec $^{-2}$ change in the overall surface brightness of the disk between epochs of observations, variability in the visibility of ansa structure(s), and azimuthally asymmetric variability of the surface brightness of these ansa(e), when they are visible. We now consider the possible origins of this variability, in the context of what is already known about the nature of the HD 163296 disk.

Previous interpretations of the bright ansae and dark zones which characterize the STIS scattered light data (Grady et al. 2000) outlined numerous mechanisms which could explain the origin of the observed phenomenon, including dynamical clearing, grain composition and/or size distribution differences, changes in the degree of disk flaring, and changes in the number density of grains. Grady et al. (2000) also postulated that, if the darker zones were in fact a partially cleared annulus, then a $\sim 0.4 M_{\text{Jupiter}}$ gas giant planet might be responsible for producing the disk clearing. While our 2003 epoch ACS F606W and F814W data clearly detected the HD 163296 scattered light disk, no evidence of any dark lanes were observed. Thus, it appears unlikely that the morphological “dark lane” identified by Grady et al. (2000) corresponds to a cleared region of the disk; we suggest that the scattered light data present no clear evidence of the presence of a planetary mass body.

We consider two classes of mechanisms which could induce variability in our scattered light observations: changes in the fundamental properties of the scatterers, and changes in the illumination of these scatterers. Our data indicate that the scattered light disk is variable on *at least* a timescale of several years, which strongly suggests that we can exclude changes in the fundamental properties of the scatterers (i.e., grain composition, grain size distribution, grain number density, and degree of disk flaring) as a plausible mechanism.

Changes in the illumination of the disk, from the perspective of the scatterers, could include either (or both) stellar variability or variations in the number of stellar photons which reach the scatterers. We are not aware of any evidence which suggests that HD 163296 experiences UX Ori–like photometric outbursts (Waters & Waelkens 1998; Dullemond et al. 2003); rather, the star appears to have a generally stable photometric brightness of $V = 6.88$, with a maximum variability range (high to low) of 0.42 mag (Herbst & Shevchenko 1999). Direct imaging of HD 163296 was obtained in each of our ACS filters at the epoch of our coronagraphic observations; however, these data were heavily saturated and did not use a gain setting which sampled the full well depth of the HRC, which would have permitted accurate photometry to be extracted (Gilliland 2004; Sirianni et al. 2005). Thus, we do not have any observational evidence which could link HD 163296's observed scattered light variability with stellar variability. Moreover, it is not clear that brightening/dimming of the central star could explain the visibility and surface brightness variability patterns observed in the disk ansae features. Rather, we suggest that HD 163296's scattered light variability is related to changes in the number of photons which reach the disk scatterers.

Self-shadowing of the outer regions of Herbig Ae disks is a phenomenon predicted by theory (Natta et al. 2001; Dullemond

et al. 2001; Dullemond & Dominik 2004a; Isella & Natta 2005), and variable illumination of envelopes has been reported in observations of GG Tau (Krist et al. 2005b) and Hubble’s Variable Nebula (Lightfoot 1989). One suggested method to produce a self-shadowed disk is by inflation of the inner disk wall, which prevents copious amounts of photons from reaching at least part of the outer (flatter) disk. Sitko et al. (2008) have noted that the infrared (IR) SED of HD 163296 can vary by $\sim 30\%$ on timescales of 3 yr or less, which they interpret as evidence of structural changes in the region of the disk near the dust sublimation zone. The mechanism driving this inner disk variability is not known, although Sitko et al. (2008) discuss several possibilities: α -disk instabilities, magnetorotational instabilities, an X-wind origin, and perturbations by a planetary-mass body. Given the noncontinuously flared geometry of the HD 163296 outer disk, as inferred from our ACS scattered light data (§ 3.1), it is plausible that even small-scale changes in the scale height of the inner disk wall could induce a variable amount of self-shadowing of the outer disk. Thus, we suggest that variable self-shadowing is one plausible mechanism which might explain the observed variability of the outer scattered light disk. Coordinated, contemporaneous observations of the inner and outer disk regions of HD 163296, namely follow-up IR SED and coronagraphic monitoring, would provide a robust means of investigating this proposed mechanism.

Recall that the bright ansa(e) features which sometimes characterize the HD 163296 scattered light disk were only observed during epochs in which the overall disk surface brightness was low (1998, 2004; see Fig. 9, and Tables 3 and 4). Thus, in our working picture of the HD 163296 scattered light disk, with admittedly few data points to work with, these morphological features are only detected during periods of enhanced self-shadowing. We suggest that the source of these observed bright features is not a density enhancement of scatterers (i.e., a clump), as one would expect such a clump would contribute a localized enhancement of scattered light not only during enhanced self-shadowing periods, but also during epochs characterized by less self-shadowing. Rather, we speculate that these bright features signify a change in the spatial distribution of the scatterers, i.e., the ansa(e) represent a region in the disk which is modestly less flattened than other surrounding locations. During periods of increased self-shadowing, these structures would partially escape the shadow created by the inner disk wall. During periods of less self-shadowing, this region would be illuminated similar to its neighboring disk regions; thus, as long as the structures do not have a significantly higher density of scatterers, the morphological feature would not be conspicuous in scattered light profiles. While the origin of the perturbations which give rise to these localized features is unknown, structure in the tenuous upper layers of protoplanetary disks is predicted to occur by theory. For example, Jang-Condell & Boss (2007) predicted that such a phenomenon would occur in the inner regions of protoplanetary disks as a by-product of planet formation via the disk instability model.

Finally, we consider the origin of the surface brightness variability of the ansa(e) structures, during the epochs in which they were visible (§ 4.2; Fig. 9). If the visibility of these features is linked to the behavior of the inner disk wall, as we have suggested, then it is likely that the surface brightness variability of these features is also linked to events in the inner disk wall region. We speculate that the inner disk wall might be azimuthally asymmetric, and hence cast an azimuthally asymmetric shadow on the outer disk. Given the orbital period of material located at the inner wall sublimation radius, ≤ 1 week (M. L. Sitko 2007, private communication), the timescale for such an asymmetry to

produce a brighter northwest versus southeast illumination (and vice versa) is much less than the maximum timescale of the observed ansa variability, several years. We suggest that a series of scattered light images of HD 163296, obtained in time steps of ~ 1 to several weeks *and* during a period of enhanced self-shadowing, would provide a direct test of our interpretation of the system.

6. SUMMARY

We have presented the first multicolor, multiepoch analysis of resolved optical scattered light imaging of the Herbig Ae star HD 163296. To summarize the observational properties of these data:

1. We spatially resolved the HD 163296 scattered light disk over radial distances of $2.9''$ – $4.4''$ (350–540 AU) in the *HST* ACS F435W, F606W, and F814W filters.
2. Radial profiles of the surface brightness along the semi-major axis of the disk follow an $\sim r^{-4}$ power-law behavior, which is indicative of a noncontinuously flared disk.
3. The $(V - I)$ color of the disk at $3.5''$, ~ 1.1 , is significantly redder than the stellar $(V - I)$ color, 0.15. This red disk color appears to be spatially uniform at the S/N of our data, and is consistent with that expected for a disk which has experienced grain growth and is at least partially self-shadowed.
4. A single ansa structure is present in the southeast disk quadrant of the 2004 epoch ACS data (F435W filter), while no structure was observed in the 2003 epoch ACS data (F606W and F814W filters), despite the fact that the limiting detection magnitude of these latter data was sufficient to probe the structure at the surface brightness observed in 2004. This morphological feature is spatially coincident with the fainter ansa reported in 1998 STIS observations (Grady et al. 2000) of HD 163296; the brighter ansae seen in the northwest disk quadrant of the STIS data are absent from our ACS epoch data.
5. The scattered light disk was observed to be significantly brighter in each of three filters of ACS observations from 2003 to 2004, as compared to white-light STIS observations in 1998. Combining the multicolor ACS data to crudely approximate the STIS bandpass suggests that the ACS epoch data are ~ 1 mag arcsec $^{-2}$ brighter than the STIS data. Along with the variability of the visibility and surface brightness of ansa structure(s) in the disk, these results *suggest that the scattered light disk of HD 163296 is variable*.

We expect that the characterization of the basic behavior of HD 163296’s scattered light disk that we have provided in this study will serve as an important foundation for future efforts to model the multiwavelength behavior of the system. Although speculative, we suggest that one plausible explanation for the origin of the observed variability is:

1. The scale height of the inner disk wall is believed to inflate and deflate on timescales of less than a few years, based on IR SED monitoring (Sitko et al. 2008). The variable scale height of the inner disk wall could induce variable self-shadowing of the outer disk, and hence produce the observed overall variability of the scattered light disk.
2. We suggest that the ansa structure(s), which appear to be discernible only during periods of enhanced self-shadowing, represent a localized region of scatterers which are at a scale height (at least marginally) above the projected shadow. As the features are not discernible during periods of more complete illumination of the outer disk, we believe that a localized enhancement in the

scale height of the disk is more likely to produce the observed phenomenon than a localized density enhancement of the scatterers (i.e., a clump).

3. The relative surface brightness variability of the northwest versus southeast ansa structures during epochs in which they are visible suggests that the inner disk wall might be azimuthally asymmetric, and hence produce an azimuthally asymmetric shadow on the outer disk. Based on the short (≤ 1 week; M. L. Sitko 2007, private communication) orbital timescale of material located at the inner wall, we suggest that a series of resolved scattered light images of HD 163296, obtained during an epoch of enhanced

self-shadowing, would provide a test of this particular suggested phenomenon.

We thank Mike Sitko, Aki Roberge, Nick Collins, and Karen Bjorkman for helpful discussions regarding this paper. We also thank our referee for providing helpful suggestions which improved the quality of this paper. Support for this project was provided by NASA NPP fellowship NNH06CC03B (J. P. W.). We acknowledge use of the SIMBAD database operated at CDS, Strasbourg, France, and the NASA ADS system.
